Autoantibodies to neurofascin induce axonal injury
Abstract

Axonal injury is considered the major cause of disability in patients with multiple sclerosis (MS), but the underlying effector mechanisms are poorly understood. Starting with a proteomics based approach we identified neurofascin (NF)-specific autoantibodies in patients with MS. These autoantibodies recognize the native form of the extracellular domains of both NF186, a neuronal protein concentrated in myelinated fibers at nodes of Ranvier, and NF155, the oligodendrocyte-specific isoform of neurofascin. Our *in vitro* studies with hippocampal slice cultures indicate that neurofascin antibodies inhibit axonal conduction in a complement dependent way. To evaluate whether circulating anti-neurofascin antibodies mediate a pathogenic effect *in vivo* we co-transferred these antibodies with myelin oligodendrocyte glycoprotein-specific encephalitogenic T cells to mimic the inflammatory pathology of MS and breach the blood-brain barrier. In this animal model antibodies to neurofascin selectively targeted nodes of Ranvier, resulting in deposition of complement, axonal injury and disease exacerbation. Together, these results identify a novel mechanism of immune mediated axonal injury that can contribute to axonal pathology in MS.
Multiple Sclerosis (MS) is characterized by repeated episodes of inflammation and demyelination in the central nervous system (CNS) with varying degree of axonal loss (1). Although chronic disability in MS was traditionally attributed to demyelination, axonal loss is now regarded as the major pathological correlate to the development of permanent neurological deficits (2;3). Axonal injury is most pronounced in regions of active inflammation and demyelination (4;5), but it is currently unknown whether this axonal pathology is due to loss of trophic support of the oligodendrocyte, toxic inflammatory mediators, or a specific immune response against axonal antigen (6-10).

The presence of immunoglobulins and complement activation products in active MS lesions (11;12) and the efficacy of therapeutic plasma exchange, or treatment with B cell depleting antibodies in some patients (13-15) provide circumstantial evidence for the involvement of antibodies in MS. However, the identity of antigens targeted by clinically relevant antibodies in MS remains obscure. Most studies have focused on the role of myelin-specific autoantigens such as myelin oligodendrocyte glycoprotein (MOG), galactosyl ceramide or sulphogalactosyl ceramide that provide targets for autoantibody-mediated demyelination in experimental autoimmune encephalomyelitis (EAE), an animal model of MS (16-21). Despite the presence of a number of studies that have documented autoantibody responses to neuronal and axonal antigens in MS, their functional significance has gone largely unexplored (9;22-25).

Our present study was inspired by findings obtained using a proteomic approach to explore the specificity of the myelin-reactive autoantibody repertoire in MS patients. We identified several patients who showed a conspicuous antibody response to neurofascin present in our myelin preparations.
Neurofascin exists in two isoforms: neurofascin 155 (NF155) is a myelin protein localized at the paranodal axo-glial junction, whilst neurofascin 186 (NF186) is a neuronal protein exposed on the surface of myelinated axons at the axonal initial segment and node of Ranvier (26). NF186 associates with the β1 and β3 chains of voltage gated sodium channels (27) and other nodal proteins to maintain the unique molecular architecture of the node of Ranvier necessary for saltatory conduction (26).

The neurofascin-specific autoantibody response in MS patients recognized the extracellular domain of both NF155 and NF186 prompting us to investigate the functional effects of such a pan-neurofascin-specific antibody response both in vitro and in an animal model. Co-transfer of a pan-neurofascin mAb together with MOG-reactive T cells demonstrated that anti-neurofascin antibodies can exacerbate disease severity in EAE by binding selectively to NF186 at the node of Ranvier. This results in acute, but reversible axonal injury and is associated with co-deposition of C9 and mouse mAb at nodes of Ranvier. In vitro the neurofascin-specific antibody was able to induce an electrophysiological deficit in hippocampal slices only in the presence of fresh sera, indicating that its pathogenic effect in vivo is complement-dependent. These observations identify NF186 as a target for autoantibody-mediated axonal injury, a novel pathomechanism that may contribute to the development of axonal pathology in MS.
Results

Identification of neurofascin as a candidate autoantigen in MS

To identify quantitatively minor myelin glycoproteins recognized by autoantibodies in patients with MS, we used a glycoprotein fraction isolated from human myelin by lentil-lectin affinity chromatography that is highly enriched for known myelin antigens such as MOG, as well as other as yet poorly characterized myelin-associated glycoproteins (Fig. 1 A). Western blotting after SDS-PAGE with sera from 22 MS patients and 21 control patients (10 other neurological diseases (OND) and 11 other inflammatory neurological diseases (OIND)) revealed a marked inter-patient variability in the immunoreactive band pattern (data not presented), but in approximately 20% of MS samples we observed a prominent response to components migrating at the molecular weight range of 150-180 kD (Fig. 1 A). To identify this protein, myelin glycoproteins were separated by 2-D gel electrophoresis, and after Western blotting probed using purified IgG (28) obtained from five MS patients, and two control donors (one with an autoimmune peripheral neuropathy, the other with cardiomyopathy). This approach identified a series of spots migrating with an apparent molecular weight of 155 kD that were recognized by the IgG fractions from all five MS patients, but neither of the controls (Fig. 1 B). Two spots were excised from the gels and the immunoreactive target was identified as neurofascin by mass spectrometry (sequence coverage of 23% and a probability of 1.9 e^{-34}).

Having identified NF155 as a candidate autoantigen in MS, we re-examined the disease-specificity of this serum antibody response in additional MS patients (n = 26), OIND patients (n = 17) and control blood donors (n = 21) by ELISA (Fig. 1 C,D). Approximately a third of MS patients and occasional OIND and control donors had a high titer response to the extracellular domain of NF155 (NF155^ED) (Fig. 1
When MS patients were stratified according to disease course, it became evident that the highest levels of NF155ED-specific antibodies were found in the sera of patients with chronic progressive disease (median OD = 0.69), as compared to relapsing remitting MS (median OD = 0.10), OIND (median OD = 0.10) and blood donor controls (median OD = 0.25). We then purified anti-NF155ED antibodies by immunoaffinity chromatography from the plasma of three representative high titer MS patients to determine whether these antibodies recognized the native protein when expressed at the surface of NF155 transfected cells. This was indeed the case, but in addition purified NF155ED-specific antibodies also bound to NF186 transfected cells as demonstrated by flow cytometry (Fig. 1 E). This cross-reactivity was confirmed by Western blotting of total brain homogenate (Fig. 1 F), and led us to speculate that recognition of NF186 at the node of Ranvier by these antibodies might exacerbate axonal injury and accelerate disease progression.

**Anti-neurofascin antibodies exacerbate clinical disease in experimental autoimmune encephalomyelitis, an animal model of MS**

To investigate this hypothesis we developed a co-transfer model of T cell mediated experimental autoimmune encephalomyelitis (EAE) (16) in which rats were injected at disease onset with the pan-neurofascin IgG2a mAb A12/18.1. This antibody mimics the properties of NF155ED-specific antibodies purified from MS patients in that it recognizes the extracellular domains of both NF155 and NF186 as demonstrated by flow cytometry of live neurofascin transfected cell lines (data not presented). Treatment with 500 μg A12/18.1 (i.p.) at disease onset resulted in a rapid and significant increase in disease severity within 24 h by when the clinical score of anti-neurofascin treated animals was 2.5 ± 0.18 (mean ± s.e.m., n = 23).
comparison, control animals injected with an irrelevant mouse IgG2a antibody had a clinical score of 1 ± 0.12 (mean ± s.e.m., n = 23) (Fig. 2 A). All animals survived this acute exacerbation of disease and began to show signs of clinical recovery 5 d post antibody transfer. The majority of animals subsequently regained complete motor function within two weeks and exhibited no residual signs of disease. However, despite exhibiting some initial signs of clinical improvement a proportion of the animals (27%, n=11) treated with A12/18.1 died suddenly during this recovery period (Fig. 2 B). This was not seen in animals treated with the control mouse IgG2a mAb, nor has it been reported in other co-transfer models of EAE. In the absence of a pre-existing inflammatory response in the CNS the transfer of the neurofascin-specific mAb into naïve recipients (n = 7) resulted in no clinical deficit.

Transfer of the pan-neurofascin-specific antibody results in acute axonal damage in the absence of demyelination, or increased inflammation in the CNS

We performed extensive histological and immunopathological analysis of the CNS to determine how A12/18.1 exacerbated clinical disease in animals with EAE. We could find no evidence that the mAb had any significant effect on either inflammation or demyelination (Fig. 2 B, Fig. 3 A-D). Comparison of the inflammatory response revealed that this was similar in both A12/18.1 treated and control animals both with respect to the numbers of inflammatory foci, as well as numbers of T cells and macrophages infiltrating the CNS (Fig. 2 B, Fig. 3 A,B). However, the disease exacerbation induced by A12/18.1 was associated with a marked increase in immunoreactivity for β-amyloid precursor protein (β-APP), a marker of acute axonal injury (Fig. 2 B, Fig. 3 E-H). The accumulation of β-APP reflects disruption of axonal transport at sites of axonal injury and was often observed in areas devoid of
infiltrating inflammatory cells in animals treated with the neurofascin-specific antibody. This was not observed in control IgG2a treated animals with EAE in which β-APP immunoreactivity was minimal and restricted to sites of perivascular and subpial inflammation. Following complete clinical recovery β-APP immunoreactivity had returned to background levels indicating resolution of axonal damage. Occasional degenerating myelin figures were observed in only one animal and we observed no obvious reduction in axonal density in the spinal cord after clinical recovery.

**Binding of antibody to neurofascin in vivo is restricted to the node of Ranvier**

Our data indicate that the clinical exacerbation induced by A12/18.1 is mediated by a direct effect of the antibody on the axon. This suggests that the primary target is NF186 at the node of Ranvier, rather than the myelin/oligodendroglial isoform of neurofascin NF155. This was confirmed by identifying sites at which A12/18.1 was bound within the CNS of animals with EAE by laser scanning confocal microscopy (Fig. 4).

Thirty hours after antibody transfer deposition of A12/18.1 was restricted to distinct bands in longitudinal sections (Fig. 4 B) or appeared as occasional circular profiles in transverse sections. No deposition of mouse IgG2a was detected in the CNS of animals injected with the control antibody (Fig. 4 A). Triple staining using antibodies to specific nodal and paranodal antigens demonstrated that deposition of the mouse neurofascin-specific mAb was restricted to nodes of Ranvier, where it co-localized with voltage gated sodium channels (Fig. 4 C-F). We observed no co-localization of adoptively transferred A12/18.1 with NF155 within the paranodal domain of myelinated fibers (Fig. 4 B), although the mAb will bind both isoforms of
neurofascin in vitro and can be used to identify NF155 within the paranodal domains of myelinated fibers in fixed tissue sections (data not presented).

In animals treated with A12/18.1 we observed a distinct halo of C9 deposition restricted to the immediate vicinity of antibody bound to the node (Fig. 4 G,H). This was not observed in animals with EAE treated with the control mouse IgG2a antibody and suggests complement may play an important role in antibody-mediated axonal injury in this model system.

**Anti-neurofascin antibodies inhibit neurotransmission in vitro**

The ability of the neurofascin-specific mAb to disrupt nerve conduction was examined in rat hippocampal slices in vitro. Perfusion of hippocampal slices with A12/18.1 (20 μg/ml) in the presence of 2.5% fresh rat serum had a significant effect on axonal conduction as measured by the presynaptic fiber volley (essentially a compound action potential) recorded from the Schaffer collateral-commissural fibers. After a variable delay of between 15 and 50 min (Fig. 5 A,B) we observed a >50% reduction in the amplitude of the fiber volley (Fig. 5 C). This effect was abolished if the serum was heat inactivated prior to the experiment at 56°C for 30 min to destroy complement (Fig. 5 C). In addition, there was no effect when the hippocampal slices were perfused with fresh serum and a control mouse IgG2a mAb (Fig. 5 C).
Discussion

Axonal loss is responsible for the development of chronic neurological deficits in MS, but the pathomechanisms that initiate or exacerbate axonal injury in this inflammatory demyelinating disease remain obscure. Previous studies demonstrated that axonal injury is most pronounced in areas of inflammatory demyelination. This led to the concept that axonal loss was a non-specific “bystander” response to inflammatory demyelination mediated by soluble factors generated by activated macrophages such as nitric oxide or T cells (10;29). However, whilst inflammatory demyelination is a ubiquitous feature of MS, axonal loss does not necessarily correlate with lesion distribution and load in defined spinal cord tracts(30) and continues despite resolution of CNS inflammation in patients with progressive disease(31;32). These observations led to suggestions that in addition to the effects of inflammation, other mechanisms are involved in the development of axonal pathology in MS.

Using an unbiased proteomic approach, we identify neurofascin as a novel target of autoantibodies in MS. Neurofascin is a member of the L1 family of cell adhesion molecules, and its two isoforms play essential roles in maintaining the structural and functional integrity of myelinated fibers (26). These isoforms are derived from a single gene by alternative splicing and their extracellular domains contain six identical Ig domains and a variable number of identical fibronectin-like repeats, and differ only in that NF155 uses an alternative fibronectin type III (FNIII) repeat and lacks a mucin-like domain (33). As a consequence, mAbs raised against these proteins are commonly cross-reactive. This is also the case for the autoantibody response to neurofascin in patients with MS, which recognizes the intact extracellular domains of both NF155 and NF186, as we demonstrate by flow cytometry.
*In vivo* in animals with EAE we demonstrate that antibodies with this specificity bind selectively to NF186 at the node of Ranvier to initiate axonal injury in the CNS and exacerbate clinical disease. The inability of A12/18.1 to recognize NF155 in these animals is presumably related to its localization within the paranodal axo-glial junctional complex. The antibody may be unable to penetrate into the junctional complexes, or alternatively, access to the target epitope is blocked owing to local protein-protein interactions. How antibody binding to the node leads to loss of function in EAE remains to be clarified. Unlike autoantibody-mediated demyelination, the clinical deficit in this model is associated with neither enhanced inflammation nor demyelination. However, the co-deposition of C9 with antibody suggests involvement of complement, as is the case in other autoantibody-mediated neurological diseases (34;35). This supposition is supported by our demonstration that A12/18.1 only mediates a functional deficit *in vitro* in the presence of fresh serum, and that this effect is abolished if the serum is heated at 56°C prior to the experiment. However, irrespective of the effector mechanisms involved, antibody-mediated axonal injury and the resulting functional deficit are reversible. Not only did the majority of animals recover clinically, but also with recovery β-APP-immunoreactivity returns to background levels, and there was no evidence of axonal loss. This suggests that the node of Ranvier is relatively resistant to antibody-mediated damage. This may involve clearance of antibody/complement complexes by endocytosis or ectocytosis (36) or up-regulation of complement inhibitors such as CD55 by neurons in EAE lesions (37).

Our experiments demonstrate that neurofascin-specific antibodies mediate axonal injury following recognition of NF186, but we cannot exclude they do not have other pathological effects. The molecular architecture of the paranode is
disrupted after both experimental demyelination (38) and in MS plaques (39-41), indicating that NF155 may become accessible to bind antibody in demyelinating lesions. Neurofascin-specific antibodies may also inhibit remyelination by binding to NF155 re-expressed on the surface of remyelinating oligodendrocytes/oligodendrocyte processes (42). Moreover, NF186 is not lost from the axonal surface following demyelination but is simply more diffusely distributed (40), suggesting it will continue to provide a target for autoantibody-mediated attack in demyelinated lesions. Neurofascin is also expressed on myelinated fibers in the peripheral nervous system suggesting that it could also be involved in the pathogenesis of autoimmune mediated peripheral neuropathies. In the current study we did not observe any enhanced β-APP immunoreactivity, or C9 deposition in the PNS, although some antibody was detected bound to nodes in root entry zones. The blood-nerve barrier is known to have a limited permeability to serum immunoglobulins at these sites (43), and in the absence of a local inflammatory response diffusion of antibody into the nerve is unable to initiate a functional deficit (44). In the absence of peripheral nerve damage the sudden death of some animals during the recovery phase of the disease cannot be explained satisfactorily, although it might reflect central autonomic dysfunction.

We demonstrate that neurofascin-specific antibodies mediate axonal damage, impair neuronal conduction, and exacerbate clinical disease in an animal model of MS, but are they relevant in human disease? In order for a circulating autoantibody response to mediate tissue damage within the CNS two criteria must be met. First, the blood-brain barrier must be breached so that autoantibodies circulating in the blood can gain access to the CNS parenchyma (12;16;45) and secondly, once within the CNS compartment the antibody must be able to access and bind to its target antigens.
In the case of the neurofascin-specific autoantibody response in MS these criteria are both met. First, MS is associated with an increased permeability of the blood-brain barrier to serum immunoglobulins (46). **In the initial inflammatory phase of MS this is most prominent in areas of perivascular inflammation. However, there is also evidence that as the disease progresses patients develop chronic blood-brain barrier abnormalities that result in increased leakage of serum protein into the CNS (47;48).** This indicates that anti-neurofascin antibodies in the periphery will gain access to the CNS parenchyma. Second, the polyclonal neurofascin-specific autoantibody response recognizes the native extracellular domain of NF186. As we demonstrate using mAb A12/18.1, these antibodies will bind to NF186 *in vivo* to exacerbate axonal injury and associated functional deficits in patients with MS. These effects will be most pronounced in patients with high titer antibody responses to NF155/186 and may have significant impact on disease progression. This may be the case in the 20 - 30 % of MS with high titer antibody responses, but it should be noted that neurofascin-specific antibodies were also detected in occasional control donors. This lack of absolute disease specificity is not unexpected and is similar to that reported for autoimmune responses to other CNS autoantigens in MS (46). In summary, we identify neurofascin as a novel autoantigen in a subset of MS patients, and demonstrate that neurofascin-specific antibodies can induce reversible axonal injury and conduction block in inflammatory demyelinating diseases of the CNS. These findings should open new perspectives for therapeutic inhibition of antibody-mediated axonal injury.
Material and Methods

Patients and control donors

In total sera from 74 patients were analyzed. These included 26 patients with MS, 17 patients with other inflammatory neurologic diseases (OIND), 10 patients with non-inflammatory neurologic diseases (OND), and 21 healthy blood donors. The MS patient group included 13 patients with definite relapsing-remitting MS, 4 patients with a clinical isolated syndrome suggestive of MS, and 9 patients with chronic progressive MS. The IgG fractions used to identify NF155 as a candidate autoantigen were isolated from patients undergoing immunoadsorption therapy (28). This study was approved by an Ethical Committee of the University of Munich.

Purification of myelin glycoproteins

Myelin was prepared according to the protocol described by Norton (49). The myelin pellet was lyophilized and stored at -80°C. A myelin glycoprotein fraction was obtained by lentil-lectin affinity chromatography according to manufacturer’s guidelines (GE Healthcare, Germany).

Gel electrophoresis, immuno-detection and mass spectrometry

Myelin glycoproteins were separated in 4-12% polyacrylamide gels (Novex, Invitrogen, Karlsruhe, Germany) and blotted to PVDF membrane. Patients’ sera were diluted 1:250 and detected with peroxidase conjugated secondary reagents and enhanced chemiluminescence.

For 2-D gel electrophoresis myelin glycoproteins were solubilized in a buffer containing 7 M urea, 2 M thiourea, 4% CHAPS, 100 mM DTT and 2% ampholytes. Glycoproteins were resolved on 17 cm IEF strips (pH range 3-10; Biorad, Munich,
Germany) and separated in the second dimension with a 7% PAGE. After electrophoresis of duplicate gels that were run in parallel one was silver stained (50), and the other blotted to PVDF membranes and immunoreactive proteins detected as described above. Spots corresponding to immunoreactive regions of the blot were excised from the silver stained gel, digested with trypsin, and analyzed by MALDI-MS. Proteins corresponding to the cleaved fragments were identified by screening the database NCBI nr using the program ProFound.

**ELISA**

96 well ELISA plates (Polyvinyl, Costar) were coated with 100 μL of 5 μg/mL NF155\textsuperscript{ED} (R & D Systems, Minneapolis, USA) or BSA (Sigma) in PBS overnight at 4°C. Patient sera were diluted 1:200 and binding was detected with anti-human IgG labeled with alkaline phosphatase (Chemicon, Chandlers Ford, UK). The antigen specific response is plotted as (mean NF155\textsuperscript{ED} OD - NF155\textsuperscript{ED} SD) - (mean BSA OD + 3 BSA SD).

**Affinity purification of anti-NF155\textsuperscript{ED} antibodies**

500 μg of recombinant rat NF155\textsuperscript{ED} was bound to an activated NHS column (Amersham, Little Chalfont, UK) according to the manufacturer’s instructions. Plasma was adjusted to pH 7.4 and run over the NF155\textsuperscript{ED} column followed by extensive washing with PBS. Bound immunoglobulins were eluted with 0.1 M glycine pH 2.7 and neutralized immediately with 1 M Tris pH 9.
Flow Cytometry Analysis

HeLa cells were transfected with NF186 in pEGFP–N1 (Clontech) or NF155 in pCDNA3.1 (Invitrogen, Paisley, UK; kindly provided by P. Brophy, Edinburgh, UK) using Lipofectamine (Invitrogen) according to the manufacturer’s instructions. Stable high expressing cell lines were selected using G418. Surface expression of NF155 and NF186 was confirmed by immunocytochemistry and flow cytometry using the pan-neurofascin mAb A12/18.1. For flow cytometry NF155 transfected, NF186 transfected or untransfected HeLa cells were diluted in FACS buffer (PBS/3% FCS) and plated out in 96 well plates at a density of 1 x 10^5 cells per well in the presence of mAb A12/18.1 or human antibody diluted to a concentration of 10 μg/mL. After incubation for 30 min on ice the cells were washed with FACS buffer, and incubated for a further 30 min on ice with anti-mouse IgG AlexaFluor488 (Invitrogen; dilution 1:250) or anti-human IgG AlexaFluor 488 (Invitrogen; dilution 1:250). After washing with FACS buffer staining was analyzed immediately on a FACalibur (BD Biosciences, Oxford, UK) flow cytometer using CellQuestPro (BD Biosciences).

Animal experiments

EAE was induced in female DA rats (6 to 8 weeks old, Harlan, UK) by adoptive transfer of 2 x 10^6 activated MOG_IgD-specific T cells as described previously (51). At the onset of clinical disease rats were injected i.p. with either the NF155/186-specific mAb A18/12 or a control mouse IgG2a antibody (Sigma, M7769). Animals were weighed and examined daily for clinical signs of EAE which was scored using the following scale: 0.5, partial loss of tail tone; 1, complete tail atony; 2, hind limb weakness; 3, hind limb paralysis; 4, fore limb paralysis; 5, moribund. In addition seven naïve DA rats were injected i.p. with 500 μg the anti-NF mAb to Autoantibodies to neurofascin induce axonal injury
investigate any possible effects mediated in the absence of a preexisting CNS inflammation.

**Immunohistology**

Animals were fixed in 4% paraformaldehyde via cardiac perfusion. Brains and spinal cords were left in 4% paraformaldehyde for 30 min prior to immersion in 30% sucrose. Tissue was then embedded in OCT and snap frozen in isopentane/liquid nitrogen. For paranodal staining sections were postfixed for 1 min in Bouin’s fixative. Prior to staining 10 μm longitudinal and transverse spinal cord cryosections were incubated in 10% normal goat serum/0.3% Triton-X 100 in PBS for 1 h. Primary antibodies were applied for 1 h at room temperature or at 4°C overnight. After washing the secondary antibodies were applied for 1 h at room temperature followed by washing and mounting in Vectashield Hardset. The sources of antibodies used in this study were: rabbit NF155-F3 (gift from Peter Brophy, University of Edinburgh, specific for the third fibronectin type III domain of NF155, 1:1,000) (52), mouse pan anti-sodium channel (IgG1, Sigma, 1:100), rabbit anti-rat C9 (1:1,000, gift from Paul Morgan, University of Cardiff, UK). Anti-mouse IgG2a Alexa-488 (1:500), anti-mouse IgG1 Alexa-633 (1:500), and anti-rabbit Alexa-568 (1:500) were obtained from Invitrogen. Paraffin sections were prepared and evaluated as previously described (53).

**Confocal Microscopy**

Images were captured using a Zeiss LSM510 META laser-scanning confocal system coupled to a Zeiss Axioplan2 upright microscope. Images were then analyzed using Zeiss LSM Image Viewer software (Carl Zeiss, Welwyn Garden City, UK).
Electrophysiology

Young adult female Lewis rats (aged 4–6 weeks) were sacrificed, and the brain was removed and placed in chilled (4–5°C) oxygenated artificial cerebrospinal fluid (aCSF). The aCSF contained: NaCl 124 mM, KCl 3 mM, NaHCO₃ 26 mM, NaH₂PO₄ 1.25 mM, D-glucose 10 mM, MgSO₄ 1 mM, and CaCl₂ 2 mM and was continuously bubbled with 95% O₂/5% CO₂. After dissecting free the hippocampus, 350 μm transverse slices were cut using a McIlwain tissue chopper. Slices were stored in a holding chamber at room temperature before being transferred to an interface type-recording chamber. Within the interface chamber, aCSF was continually perfused below the slice at a rate of 1–2 ml/min and at a constant temperature of 27–29°C.

Legends to Figures

Figure 1: Antibodies to NF155 and NF186 are present in patients with multiple sclerosis.

(A) Human myelin and the myelin glycoprotein (gp) fraction were separated by SDS-PAGE, blotted, and glycoproteins detected using biotinylated lentil-lectin. The myelin glycoprotein fraction is highly enriched in higher molecular weight glycoproteins (left panel). Using this myelin glycoprotein fraction to screen patient sera by Western blotting identified antibody responses to a variety of components, including a protein migrating with an apparent molecular weight of approximately 155 kD (right panel).

(B) Two 2D gels were run in parallel. One was silver-stained (left panel), the other one blotted and developed with IgG obtained from an immunoadsorption eluate of an MS patient (right panel). The encircled spots at 155 kD were excised, and identified by MALDI-MS as neurofascin. (C) Serum IgG antibody titers to recombinant NF155ED were measured by ELISA in OIND (n=17) and MS (n=26) patients stratified by disease course. Patients with chronic progressive MS (MS-CP) had the highest median antibody response to NF155ED and this was significantly higher than in OIND. * p<0.05 as compared by Mann-Whitney U-test. (D) The titrations of three sera from high titer MS patients and one negative control donor are shown. (E) Anti-NF155ECD antibodies affinity purified from plasma of an MS patient bind to both isoforms of neurofascin when expressed at the surface of transfected cells (left panel NF155, right panel NF186) as shown by flow cytometry. The open graph represents the staining of the control cell line, the closed graph of the NF-transfectants. (F) Rat brain homogenate was separated by SDS-PAGE, blotted, and probed with either the neurofascin-specific mAb A12/18.1 or the purified anti-NF155ECD antibodies indicating recognition of both the 155 kD and the 186 kD isoforms.
Figure 2: Passive Transfer of anti-neurofascin antibody exacerbates adoptive transfer EAE

(A) Rats injected with 2 x 10^6 activated MOG^{iβD}-specific T cells followed by 500 μg of the IgG2a control antibody on d 4 (white circles) reached a maximum clinical score of 1 +/- 0.12 and had completely recovered by day 10 post T cell transfer. Disease activity was exacerbated in rats co-injected with anti-neurofascin mAb (black squares). These animals reached a maximum clinical score of 2.7 +/- 0.17 and clinical recovery was still incomplete 20 d post T cell transfer. Mean ± s.e.m. (n=11). Pooled data from independent experiments are shown. (B) Co-transfer of the NF155/186-specific mAb in rats with adoptively transferred EAE increased disease severity without exacerbating either inflammation or demyelination in the CNS. Clinical data are pooled from independent experiments. Histological data were obtained from animals sacrificed 48 h after mAb injection. Data are reported as the mean ± s.e.m.

Figure 3: Pathology associated with autoantibody-mediated axonal injury in adoptive transfer EAE

Representative histopathology of the spinal cord 2 d after transfer of either anti-neurofascin antibody (B, D, F, H) or an IgG2a control antibody (A, C, E, G).

A, B. H&E staining reveals the presence of similar numbers of inflammatory infiltrates (indicated by arrows) in animals co-injected with (A) control mAb and (B) NF155/186 specific mAb. The areas indicated by arrowheads in A and B are shown in immunohistochemical staining for β-APP, (E and F) at higher magnification. C, D. Luxol Fast Blue staining for myelin (blue/turquoise) reveals that demyelination is not enhanced by the anti-neurofascin mAb. In E-H β-APP
is stained brown by immunohistochemistry and cell nuclei are counterstained blue with hematoxylin. This staining for β-APP, which indicates acute axonal injury, reveals numerous injured axons (brown dots in cross sections (F); brown fibers in longitudinal sections (H) in animals treated with the NF155/186-specific mAb. Note that in comparison to animals treated with the NF155/186-specific mAb (F, H), axonal injury is virtually absent in animals receiving the control IgG2a mAb (E, G). Magnifications: A-D: x 45; F-H: x 350, inserts x 800.

Figure 4: The pan-neurofascin-specific mAb A12.18/1 binds selectively to the node of Ranvier in vivo in animals with EAE

Confocal microscopy of representative spinal cord tissue from animals with EAE 30 h after transfer of anti-NF155/NF186 mAb A12.18/1 (B-H) or IgG2a control antibody (A). Co-transfer of anti-NF155/NF186 mAb resulted in deposition of the antibody within discreet regions of the CNS when visualized with an Alexa-488 conjugated anti-mouse IgG2a antibody (green). Double staining with a rabbit antibody to NF155 (red) identified the paranodal domains of myelinated axons and demonstrated that the injected mAb did not co-localise with NF155 but was deposited between adjacent paranodes (B). There was no deposition of mouse antibody in the CNS of animals injected with the isotype control antibody when visualized with an Alexa-488 conjugated anti-mouse IgG2a antibody (green) as shown in relation to NF155 staining at the paranode (red) (A). Triple staining (C-F) for voltage gated sodium channels (C, blue), bound anti-NF155/NF186 mAb (D, green) and NF155 (E, red) confirm that the adoptively transferred mAb binds selectively at the node of Ranvier. (F) Merged image of (C-E). Deposition of the in vivo injected anti-neurofascin mAb at the node of Ranvier is accompanied by the deposition of complement C9. Sections were

stained with an Alexa-488 conjugated anti-mouse IgG2a antibody to identify bound anti-neurofascin mAb (green), and a rabbit anti-rat C9 antibody (red) (**G,H**). Bar represents 5 μm in all panels.

**Figure 5: Anti-neurofascin antibody disrupts nerve conduction in vitro**

(A) An example of the field potential recorded under control conditions from the CA1 region of a rat hippocampal slice in a single slice using a single stimulus of the Schaffer collateral-commissural fibers every 30 s (top trace) is shown. Perfusion of the anti-neurofascin mAb A12/18.1 plus normal rat serum causes a decrease in the fiber volley amplitude (middle trace) which can be clearly seen when the traces are overlaid (bottom trace). (B) Time course data showing the effect of A12/18.1 antibody and serum on the amplitude of the fiber volley (mean ± s.e.m, n=5). (C) A decrease in fiber volley amplitude after 1 h perfusion of the treatment is only seen when A12/18.1 is applied in the presence of fresh rat serum. There is no effect on the fiber volley amplitude if A12/18.1 and heat inactivated (HI) serum is applied or if a control IgG2a antibody and fresh serum is applied. n=5 for all treatments. Significance is determined by a paired t-test on the raw (not normalized) data. p = 0.012 for A12/18.1 antibody and fresh serum.
